I. INTRODUCTION

Traditionally, transverse magnetic focusing (TMF) experiments have been restricted to unipolar conduction, in mediums such as metals [1] and two-dimensional electron gases (2DEGs) [2]. The discovery of graphene [3], in which electrons behave as massless Dirac fermions [4], has provided an exciting new platform for studying TMF. Graphene’s gapless band structure, allowing ambipolar conduction, has enabled several recent TMF experiments. TMF in graphene has been studied as a function of carrier density [5] and imaged with scanning gate microscopy [6]. In addition, a large number of TMF peaks have been observed in graphene and hexagonal boron-nitride superlattices [7]. Recently, p-n junctions in graphene have been used in TMF experiments to steer the focused beam [8], opening the door to new electron optics. The p-n junction is a fundamental device and has received a significant amount of attention from the graphene community. Graphene p-n junctions have rich physical properties, exhibiting chiral tunneling [9,10], angle-dependent transmission [11–13], quantized conductance in high magnetic fields [14–16], and ballistic interference [17].

In this paper, we use quantum transport methods to model the graphene p-n junction TMF experiment of Chen et al. [8]. Our calculations, implemented in the KWANT package [18], intrinsically capture quantum interference, tunneling, and angle-dependent transmission [19], which enables us to explain the results of Chen et al. [8] in a completely quantum mechanical framework, without any fitting parameters. Previously, we have used the same basic model to understand Hall measurements in graphene p-n junctions [20]. By including large dephasing edge contacts and performing multiterminal Landauer-Büttiker analysis [21], we are able to capture both the in-resonance and off-resonance characteristics of the device. We achieve exceptionally strong agreement between our simulation and experiment [8], as shown in Fig. 7.

When a magnetic field is applied perpendicular to a graphene p-n junction, electrons transporting across the junction will form snake states, arcing between the p and n sides of the junction [22]. In graphene, the arcs are characterized by the cyclotron radius, given by $r_c = \frac{\hbar \sqrt{m^*}}{eB}$, with $\hbar$ the reduced Planck’s constant, $n$ the carrier density, $e$ the electron charge, and $B$ the applied magnetic field. Snake states have been observed along graphene p-n junctions in several experiments [23–25]. Additionally, the transport of electrons in snake states has been modeled using quantum mechanical [24,26–28] and semiclassical [29–34] methods.

The TMF experiment performed on graphene p-n junctions by Chen et al. [8] probes a special case of snake-state transport, in a device similar to that depicted in Figs. 1(a) and 1(b). The device studied by Chen et al. [8] is special because the distance between contacts on each side of the junction, $D_C$, is approximately equal to the width of the device, $W$. When $2r_c \approx D_C$, the applied magnetic field focuses electrons directly between the contacts. In a unipolar system, the carriers are directed back to the side from which they originate. Conversely, in a p-n junction, the carriers will be steered towards the opposite side of the device. These two paths are depicted in Fig. 1(a).

II. TRANSPORT MODEL

In this paper, we study a tight-binding Hamiltonian describing low-energy electrons in graphene, given by

$$\hat{H} = \sum_{i} \epsilon_i \hat{c}_i^\dagger \hat{c}_i + \sum_{i,j} t_{i,j} \hat{c}_i^\dagger \hat{c}_j, \quad (1)$$

where the second summation only takes place for atoms which are first-nearest neighbors. $\hat{c}_i^\dagger / \hat{c}_i$ are Fermionic creation/annihilation operators, $\epsilon_i$ is the on-site energy at site $i$, and $t_{i,j}$ is the hopping energy between sites $i$ and $j$. The effect of an applied magnetic field is included using Peierl’s substitution, $t_{i,j} = t_{i,j} \exp[i \hat{f}_i \int_{\gamma_i} A \cdot d\mathbf{r}]$, where we adopt a Landau gauge inside the channel, $A = (-By,0)$, and a circular gauge for the vector potential in the leads $A(x,y) = -B(r \cdot e_2)e_1$ [35]. Keeping with the notation in [35], $e_1 = (\cos \theta, \sin \theta)^T$ and $e_2 = (-\sin \theta, \cos \theta)^T$ where $\theta$ is the angle of a particular lead measured relative to the $x$ axis. We use a scaled tight-binding model [36] where $a = s_f a_0$ and $t_{i,j} = t_{i,j}/s_f$. The term $s_f = 10$ scales the lattice constant $a_0$ and

the atomistic hopping energy $t_0 \approx 2.7$ eV [37] to yield more efficient simulations.

We simulate a six-terminal Hall bar, as depicted in Fig. 1(b), with four small contacts (labeled one, two, four, and five) and two large contacts (labeled zero and three). The spacing between the inner edges of the small contacts is set equal to the width of the Hall bar, $D_C = W = 200$ nm, $D_W = 50$ nm, and $L_C = 60$ nm. The red rectangles indicate dephasing contacts used in the simulation.

FIG. 1. (a) Model of the graphene device depicting the first TMF resonance for $p$-$p'$ and $p$-$n$ junctions. The graphene devices we compare with in this paper were encapsulated by hexagonal boron nitride; however, since we do not consider that crystal in our model, we only depict the graphene lattice. (b) Schematic of device with four-terminal measurement configuration. The simulated device has dimensions $D_C = W = 200$ nm, $D_W = 50$ nm, and $L_C = 60$ nm. The red rectangles indicate dephasing contacts used in the simulation. (c) Real-space energy band diagram of the device.

The on-site energy where they are connected to the channel.

The summation takes place over all leads in the system, including the dephasing contacts. For our simulation, (2) generates a system of six linear equations with six unknowns. The term $T_{qp}$ is the quantum mechanical transmission function from lead $p$ to $q$, defined as

$$T_{qp}(E) = \sum_{n \in p, m \in q} |S_{nm}(E)|^2,$$

where $S_{nm}$ is the scattering matrix element between the $n$th and $m$th transverse modes in leads $p$ and $q$, respectively. The summation in (3) takes place over the available modes in each lead at energy $E$.

To connect with the multiterminal measurement of Chen et al. [8], we simulate driving a current between contacts one and five and calculate the voltage acquired by contacts two and four. Practically, this requires setting $I_1 = -I_5$, $I_0 = I_2 = I_3 = I_4 = 0$, and choosing a contact to be grounded, in this case $V_1 = 0$. The nonlocal resistance for this configuration is defined as

$$R_{15,24} = \frac{V_2 - V_4}{I_1 - I_5}.$$

The components of (4) are attained by solving the linear system, $I = \frac{2e^2}{h} TV$, defined by (2), where $I$ and $V$ are column vectors of lead currents and voltages, respectively, and $T$ is a matrix of transmission functions. Making the substitutions above, (4) may be reduced to $R_{15,24} = \frac{h}{2e^2} \left( R_{15} - R_{25} \right)$. $R_{35}$ and $R_{25}$ are elements of the $R$ matrix, defined as $R = T^{-1}$, and are entirely comprised of transmission functions between different leads; thus, the problem is reduced to calculating the permutations of (3).

To understand the terminal characteristics of our simulation, we generate spatially resolved particle current density maps using

$$J_{r,x}(E) = -2 \sum_{n,p} \text{Im}[\psi_n(r_i, E) \hat{H}_{ij} \psi_n(r_j, E)],$$

where $r_i$ is the position of the $i$th lattice site, and $\psi_n(r_i, E)$ is the wave function of the $n$th conducting mode in lead $p$. The summation takes place over all conductive modes in lead $p$ available at energy $E$. By solving the scattering problem for each transverse mode separately, we are able to extract the contribution of each mode to the total current density [43–45]. Spatially resolved particle current density maps have been
FIG. 2. Maps of local particle current density (5) for a $p$-$p'$ [$p$-$n$] junction in (a) [(b)] the first TMF resonance and (c) [(d)] the second TMF resonance. Darker colors indicate higher magnitude of local particle current density. The $p$-$p'$ junctions in (a) and (c) are configured as $E_1 = 50$ and $E_2 = 75$ meV. For the first $p$-$n$ TMF resonance in (b), the junction is configured as $E_1 = -E_2 = 50$ meV. The second $p$-$n$ TMF resonance in (d) is configured as $E_1 = 50$ and $E_2 = -100$ meV. The scale bars of all figures in this paper are 60 nm.

useful in the past for understanding transport in graphene subjected to a magnetic field [46].

III. RESULTS AND DISCUSSION

In Fig. 2, we plot vector flow maps of the local particle current density (5) injected by contact one for $p$-$p'$ and $p$-$n$ junctions. All of the scale bars presented in this paper are 60 nm and darker colors indicate higher magnitudes of local particle current density. When current is focused into contact two (four), we observe positive (negative) peaks in the nonlocal resistance, respectively.

When the $p$-$p'$ junction is in the first TMF resonance, in Fig. 2(a), carriers injected by contact one are directed directly into contact two. The carriers are injected and take on a broad spread of angles in the channel, but are primarily focused into a bright caustic which enters contact two. The junction redirects the carriers slightly, elongating the orbit. Due to the small size of the contacts, not all carriers which are injected by contact one are collected at contact two. Some carriers reflect off the bottom edge of the device, resulting in the interference fringes seen on the caustic, and then skip into contact three.

For the first resonance of the $p$-$n$ junction, in Fig. 2(b), current injected from contact one is focused directly into contact four. The 50 nm junction width acts as a low-pass filter, allowing only current flowing close to normal to the junction to transmit. On the left side of the junction, wave interference patterns indicate the current density reflected off the junction, which then exits out the contacts on the left side of the device. The transmitted current predominately focuses into a caustic which enters contact four.

At low magnetic fields, a significant portion of the current injected from contact one hits the top edge of the device before crossing the junction, as seen for the $p$-$n$ junction in Fig. 2(b). This is a consequence of the device geometry studied by Chen et al. [8] and increasing the device width to avoid hitting the top edge prohibits one from probing the first $p$-$n$ TMF resonance. Interestingly, a component of the current hitting the top edge is redirected and transmits across the junction. This subtle detail, captured by our model, contributes to the device’s terminal characteristics and is important in many of the different junction configurations.

When the magnetic field is increased to the second TMF resonance, in Figs. 2(c) and 2(d), the current density will skip along the edge of the junction ($p$-$n$ case) or the edge of the device ($p$-$p'$ case). $p$-$n$ junctions do not exhibit the second resonance until the $n$ doping is stronger than the $p$ doping, thus we configure the junction in Fig. 2(d) as $E_1 = 50$ and $E_2 = -100$ meV. In the $p$-$n$ configuration, on the $p$ side, the current forms a circular orbit which reflects near the bottom of the junction and again almost halfway up. At each of these points, there is a significant portion of current which is incoming normal to the junction and transmits to the other side, focusing on contact four. Due to the filtering effect of a smooth $p$-$n$ junction, the second TMF resonance is significantly weaker.

To further understand the local particle current density of the devices in Fig. 2, in Fig. 3 we resolve the characteristic by each propagating mode. By resolving each mode which contributes to the results in Fig. 2, we observe a combination of features reminiscent of semiclassical skipping orbits and quantum mechanical interference patterns.

The lowest mode is injected straight into the device, perpendicular to the semi-infinite contact. In the first resonance of the $p$-$p'$ and $p$-$n$ junction, shown in columns one and three of Fig. 3, respectively, the lowest mode is bent so that the wave is propagating approximately normal to the junction when it crosses it. Thus, the lowest mode is nearly perfectly transmitted, with very few reflections (indicated by interference fringes) visible. Transport similar to what the lowest mode displays in our simulations was demonstrated recently in a proposal for a parabolic $p$-$n$ junction surrounding a contact, which filters carriers such that the only current injected to the device is traveling parallel to the contact [40].
FIG. 3. Table of mode-resolved particle current density for each panel of Fig. 2. The modes of each column are summed to give the final result in Fig. 2. By looking at each mode individually, the interplay between the semiclassical and quantum mechanical nature of the system is visible.

Higher modes are injected into the device with nonzero angles and arrive at the junction traveling at oblique angles. For the first resonance of the $p$-p', the beam is noticeably refracted as it crosses the junction. In the $p$-n junction, the higher-order modes have significant components which are reflected off the junction, due to the angle-dependent transmission across the junction.

For the second resonance of the $p$-p' and $p$-n' configurations, the local particle current density patterns in Fig. 2 are more complex than the first resonance. By resolving each mode, we are able to develop a better picture of the important transport mechanisms. The higher-order modes for the $p$-p' junction have a component which transports nearly parallel to the lower edge of the device. This is particularly evident in the fourth and fifth modes. Most of the carriers which transport in this manner will miss contact two and transmit out contact three, resulting in a weaker signal for the second focusing resonance.

The second focusing resonance of the $p$-n' displays the most complex characteristics of the device, with predominant quantum characteristics not present in the other configurations. At the higher magnetic field, the first and second modes appear to begin to form Landau levels when they collide with the junction, similar to what we have studied in our previous work [20]. The higher-order modes, however, show a more complex, swirling pattern. The carriers transport in skipping orbits which partially reflect off the junction, interfering with themselves. A portion of each orbit transmits across the junction, contributing to the second $p$-n' resonance.

As mentioned previously, the dephasing edge contacts (labeled contact zero and three) are critical to attaining the results presented in this paper. To demonstrate this importance, in Fig. 4 we plot the local particle current density for the

FIG. 4. Comparison of particle current density for the device configured as in Fig. 2(b), both (a) with and (b) without dephasing edge contacts. When the dephasing edge contacts are removed, in (b), carrier density which is not focused into contact four will skip around the edge of the device until it exits out one of the small contacts. The carrier density, which is not dephased, will interfere with the incoming waves and destroy the resonance condition. This results in the extremely chaotic pattern seen in (b), with no observable focusing resonances.
device configured as in Fig. 2(b), both with and without the dephasing contacts. When the dephasing contacts are removed, in Fig. 4(b), the portions of the wave which normally exit contacts zero and three instead scatter around the edge of the device. The wave will continue to scatter around the device, interfering with itself, until exiting out one of the small contacts. This process occurs until the device reaches the steady state, resulting in the extremely chaotic pattern shown here.

Figure 5 shows the nonlocal resistance (4) and selected transmission coefficients (3) as a function of magnetic field for an asymmetric $p$-$p'$ junction and a symmetric $p$-$n$ junction. The two junction configurations are doped the same as in Figs. 2(a) and 2(b), respectively. For the relatively small magnetic fields considered in this paper, the orientation of the edges has been shown to have a minimal effect on the TMF characteristics [39]; switching the edge types in our model, no dephasing happens along the junction, the edges has been shown to have a minimal effect on the TMF characteristics [39]; switching the edge types in our model, no dephasing happens along the junction, the device enters the quantum Hall regime. This effect is also the reason why we do not see a well-defined peak in resistance at $B = 0.128 \, \text{T}$, shown in Fig. 5(b). The important transmission function for understanding the resonance condition of the $p$-$n$ junction is $T_{p}$, which is peaked while the device is in resonance.

When either configuration of junction is not in resonance, there is an increase in the transmission from contact one into contact three, $T_{n}$. In the off-resonance state of the $p$-$p'$ junction, carriers which are not focused from contact one into two will hit the bottom edge of the device and skip into contact three. To maintain current conservation, the carriers will be reinjected by the floating contact three and the magnetic field will direct the carriers towards contact four, resulting in the negative off-resonance resistance in Fig. 5(a). Conversely, in the $p$-$n$ junction, carriers which miss contact four will skip along the top edge of the device. Again, they will be dephased by contact three, except this time the reinjected carriers will be directed towards contact two, which results in the positive off-resonance resistance in Fig. 5(a). In Fig. 6 we illustrate the off-resonance particle current density for a symmetric $p$-$n$ junction.

The junction filtering effect, seen in Fig. 2, results in significantly weaker and fewer TMF resonances when the device is in the $p$-$n$ configuration. For the symmetric $p$-$n$ junction, in Fig. 5, only a single well-defined resonance is observed. At higher magnetic fields, the beam of carriers skips along the edge of the junction; each time the beam hits the junction, only a very small amount will leak through. Since, in our model, no dephasing happens along the junction, the reflected wave of carriers will interfere with itself, further disrupting any resonance from setting up.

In addition, the nonlocal resistance tends towards zero for each configuration at around $B = 0.65 \, \text{T}$. This is due to the carriers being forced into edge states as the device enters the quantum Hall regime. This effect is also the reason why we do not see a well-defined peak in $T_{p}$ for the third TMF resonance of the $p$-$p'$ junction configuration. Capturing this feature highlights the power of quantum transport modeling, where our simulations smoothly transition between carriers occupying semiclassical skipping orbits and edge states.

Finally, in Fig. 7, we compare our model with the recent experimental data of Chen et al. [8], reproduced with copyright permission. In Fig. 7(a), we fix the doping of the left side of the junction to $E_{1} = 50 \, \text{meV}$ ($p$ type) and vary the doping...
FIG. 6. Off-resonance condition particle current density for the symmetric p-n junction studied in Fig. 2(b). The junction is configured as $E_1 = -E_2 = 50$ meV. (a) $B = 0.11$ T; (b) $B = 0.16$ T. When the magnetic field is not strong enough to focus the carriers into contact four, the transmitted wave collides with the top of the device, to the right of contact four, and skips into contact three. When the magnetic field is too strong, as in (b), the transmitted wave is focused to the left of contact four and again skips into contact three.

of the right side of the junction and applied magnetic field simultaneously. The fixed doping on the left side of the device mimics the experiment of Chen et al., where the carrier density of one side of their device was fixed by a buried graphite gate [8]. For each configuration, we calculate the nonlocal resistance (4) as before. We report the doping of the right side in terms of carrier density $n$, which has a similar functional form to the gate voltage applied in experiment. For a clearer comparison with the experimental data, in Fig. 7(a) we have switched to reporting resistance in terms of Ohms.

Our simulation results show a striking similarity to the experimental data, capturing all of the major features. These include the four unipolar junction TMF resonances, the first ambipolar TMF resonance, and the negative and positive peaks in resistance when the unipolar and ambipolar configurations are not in resonance, respectively.

We also are able to explain a number of subtle features seen experimentally which are due to the transitions between different types of junctions. The second negative peak in the unipolar junction configuration begins to disappear as the right side of the device is more strongly doped p type. As the p-type doping of the right side of the junction is increased, this transition occurs as the device goes from a $p-p^-$ junction, to a uniformly doped $p$ type, to a $p-p^+$ junction. In the experimental data of Chen et al. in Fig. 7(b), this transition occurs around $V_{Si} = -20$ V [8].

The second ambipolar junction TMF resonance in Fig. 7 is extremely weak until the n-type doping of the right side of the junction exceeds the fixed p-type doping. This effect is enabled by the increased number of modes available to conduct on the right side of the junction as the doping is increased. The filtering effect due to the large junction width present in our model and in experiment [8] prohibits the traditional picture of the carrier density snaking across the junction several times in the second TMF resonance. Instead, the resonance has the characteristic of the flow map shown in Fig. 2(d).

In Fig. 7(b), there is a slight discontinuity observed in the second positive magnetic field TMF resonance of the $p-p^+$, near $V_{Si} = -10$ V. Additionally, in the negative magnetic field half of the map, the $p-p^-$ resonances tend to begin at higher values of $V_{Si}$ than for positive magnetic fields. These effects are likely due to asymmetry in the potential profile of the $p-p'$ junction formed by the silicon back-gate or graphite buried gate structure used by Chen et al. [8]. When $V_{Si}$ is very small compared to the buried gate, the asymmetry of the junction potential will be the most pronounced. In our model, we have always assumed a symmetrically formed junction, and thus do not capture this effect.

Here, we will address the effect of scaling down the device measured by Chen et al. for our simulations [8]. In order to keep the lattice scaling factor in the tight-binding model...
down to a reasonable value, it is necessary to scale the size of the simulated device down. Our simulated device is about a factor of ten smaller than the micrometer-scale device measured experimentally [8]. This scaling still allows us to qualitatively match our simulation to the experimental data, but not quantitatively.

Two quantitative differences between our simulation and experiment are introduced by scaling down the simulated device. First, in our simulation, a larger magnetic field must be used. The cyclotron radius in graphene is proportional $1/|B|$, and therefore the reduced distance between measurement probes in our simulations necessitates a higher magnetic field than used in experiment.

Additionally, the difference in device size and contact dimensions results in a simulated resistance of about 20 times larger than what was observed experimentally [8]. The reduced contact dimension limits the number of conductive modes available in the contacts, resulting in the large value in our simulated resistance. Scaling up the simulated device would result in a lower resistance; however, the size used in this work is sufficient for understanding the physics in play. Qualitatively matching the experimental results, as in Fig. 7(a), is enough for the concepts we have discussed to be applied to understand the experimental measurements of Chen et al. [8].

In conclusion, we demonstrate a quantum transport model for a TMF experiment on graphene $p$-$n$ by Chen et al. [8]. Spatially resolved particle current density flow maps reveal the behavior of carriers in the first and second resonances of $p$-$p'$ and $p$-$n$ junctions. Our results demonstrate the importance of wave interference and junction filtering effect for understanding TMF experiments. A combination of dephasing edge contacts and use of the Landauer-Büttiker formula supplementing the standard tight-binding model yield extremely close agreement with experiment. Our nonlocal resistance simulations show well-defined positive and negative peaks, which are due to enhanced transmission into contacts three or four, respectively. Many of the features seen by Chen et al. [8] have been explained, including the transition into the quantum Hall regime for high magnetic fields and the transitions between different $p$-$p'$ and $p$-$n$ doping regimes.
